# CS711008Z Algorithm Design and Analysis

## Lecture 11. Approximation algorithm: a brief introduction

Dongbo Bu

Institute of Computing Technology  
Chinese Academy of Sciences, Beijing, China

- Introduction and the first example: `MAKESPAN` problem;
- The key idea in approximation algorithm design: 1) constructing a feasible solution, and 2) “comparing with lower bound of `OPT`” rather than “comparing with `OPT`”;
- How to find a lower bound of `OPT`? Combinatorial technique, LP-based techniques (LP-relaxation, duality, etc.);
- `SETCOVER`: a good example to demonstrate four techniques: Greedy, LP+Rounding, Dual-LP+Rounding, Primal\_and\_dual;
- Other techniques: scaling for `KNAPSACK`, pruning for `K-CENTER`, `TSP`, `DISJOINTPATHS`;

The process of design of approximation algorithm is not very different from that of design of exact algorithms. It still involves unraveling the problem structure and finding algorithm techniques to exploit it.

How to deal with hard problems?

# How to deal with hard problems?

- Most natural optimization problem, including those arising in important application areas, are NP-Hard.
- It is widely believed that there is no efficient algorithm to a NP-Hard problem.
- Recall that **efficient algorithm** refers to a **polynomial-time deterministic** algorithm to find **optimal** solution even in **worst case**.
- How to deal with hard problems? Trade-off “quality” and “time”.

# Trade-off “quality” and “time”

We have a couple of options:

- ① Give up **polynomial-time** in **worst-case** restriction: though our algorithm takes exponential time in the worst case, we hope that the algorithm run fast on the practical instances, e.g. branch-and-bound, branch-and-cut, and branch-and-pricing algorithms are used to solve a TSP instance with over 24978 Swedish Cities (see <http://www.tsp.gatech.edu/history/pictorial/sw24978.html>)
- ② Give up **optimum** restriction: from **optimal** solution to **nearly optimal** solution in the hope that **nearly optimal** is easy to find, e.g. approximation algorithm (with theoretical guarantee), heuristics, local search (without theoretical guarantee);
- ③ Give up **deterministic** restriction: we hope that the expectation of running time of a randomized algorithm might be polynomial;

## Approximation strategy

*Although this may seem a paradox, all **exact** science is dominated by the idea of **approximation**.*

— B. Russel

- Why do we study approximation algorithms?
  - 1 As an algorithm with theoretical guarantee;
  - 2 As a core algorithmic idea to solve practical problems after fine tuning;
  - 3 As a mathematically rigorous way to analyze heuristics;
  - 4 As a way to explore deeper into the combinatorial problem structure, to uncover problem structure;

## Definition ( $\alpha$ -approximation algorithm)

An algorithm is an  $\alpha$ -approximation algorithm for a minimization problem if:

- 1 Time: the algorithm runs in polynomial time;
- 2 Quality: the algorithm outputs a solution  $S$  whose value is within a factor of  $\alpha$  of the value of optimal solution (denoted as  $OPT$ ), i.e.  $Value(S) \leq \alpha OPT$ .

## Definition (PTAS)

A *PTAS* (*polynomial time approximation schema*) for a minimization problem is a **family** of algorithms  $\{A_\epsilon : \epsilon > 0\}$  such that for each  $\epsilon$ ,  $A_\epsilon$  is a  $(1 + \epsilon)$ -approximation algorithm running in polynomial time in input size.

The first example: MAKESPAN problem

# MAKESPAN (LOADBALANCE) problem

- Practical problem:
  - We have multiple servers to process a set of jobs. Intuitively, we try to make the loads as balanced as possible.
  - How to schedule jobs to machines to finish all jobs as early as possible?

# Problem statement

## INPUT:

$m$  servers  $M_1, M_2, \dots, M_m$ ,  $n$  jobs (each job  $j$  has a processing time  $t_j$ );

## OUTPUT:

An assignment of jobs to machines to minimize the *makespan*, i.e. the maximum load on any machine,  $T = \max_i \sum_{j \in A(i)} t_j$ , where  $A(i)$  denotes the jobs assigned to machine  $i$ .

# Hardness of MAKESPAN problem

## Theorem

MAKESPAN is a NP-Complete problem.

## Proof.

- We will prove that  $\text{PARTITION} \leq_P \text{MAKESPAN}$ .
- **Transformation:**  
Given an instance of PARTITION problem, we construct an instance of MAKESPAN problem as follows:
  - 1 For each number  $s_i \in S$ , new a job  $i$  with  $t_i = s_i$ ;
  - 2 The objective is to find a schedule of these jobs on 2 machines with makespan  $T = \frac{1}{2} \sum_i t_i$ .
- **Equivalence:** It is obvious that a partition corresponds to a schedule.

# Greedy technique for MAKESPAN problem

- **Key observation:** solution is a partition of jobs, or  $X = (x_1, x_2, \dots, x_n)$ , where  $x_i = 1, 2, \dots, m$ .
- Basic idea: Let's describe the solving process as a series of decisions. At each decision step, we assign a job to a machine. Consider a specific job. We have  $m$  options.
- Greedy rule: To make loads as balanced as possible, it is reasonable to assign a job to the machine with the smallest load.

## GREEDYMAKESPAN1 algorithm

- 1: **for**  $i = 1$  to  $m$  **do**
- 2:    $T_i = 0$ ; //  $T_i$  denotes the load of machine  $i$ ;
- 3:    $A_i = \text{NULL}$ ; //initializing all machines with 0 jobs;
- 4: **end for**
- 5: **for**  $j = 1$  to  $n$  **do**
- 6:   Let  $k = \arg \min T_i$ ;
- 7:    $A_k = A_k \cup \{j\}$ ; //assigning job  $j$  to machine  $M_k$
- 8:    $T_k = T_k + t_j$ ;
- 9: **end for**

# An example

6 Jobs

3 Machines

- Let  $T$  be the makespan reported by GREEDYMAKESPAN1 algorithm, and  $OPT$  be the optimal makespan.
- The objective is to measure the quality of  $T$  via comparing  $T$  with  $OPT$ .

$2*OPT$  —————

- In the example, GREEDYMAKESPAN1 reports  $T = 8$ , which is not too bad since  $T$  will not be greater than  $2OPT$ .

# Using a lower bound of $OPT$ rather than $OPT$ itself

- But how can we compare  $T$  against  $OPT$  while  $OPT$  is yet unknown?
- Note that though it is difficult to know  $OPT$ , it is usually easy to obtain a lower bound of  $OPT$ .
- Thus we can use the lower bound as a bridge to build connection between  $T$  and  $OPT$ . More specifically, we compare  $T$  with the lower bound of  $OPT$  rather than compare  $T$  with  $OPT$  directly.

# Finding a lower bound of $OPT$

- Take **MAKESPAN** problem as an example.
- Though  $OPT$  is unknown, we can easily set lower bound of  $OPT$  as follows:
  - 1 Key observation 1:  $OPT \geq \frac{1}{m} \sum_j t_j = \frac{19}{3}$ .
  - 2 Key observation 2:  $OPT \geq t_j$  for any  $j$ ; thus,  $OPT \geq 6$ .

# MAKESPANALGO1 is not too bad

- Using the lower bounds as bridge, we can prove the following theorem:

## Theorem

$T \leq 2OPT$ , i.e. GREEDYMAKESPANALGO1 is a 2-approximation algorithm.

2\*OPT

## Proof.

- Let  $M_i$  be the machine with the heaviest load  $T$ ;
- Divide  $T$  into two parts: the last job  $k$ , and the previous jobs. Thus  $T = t_k + A$ , where  $A$  denotes the total load of the previous jobs.
- We have  $T \leq 2OPT$  since
  - 1  $t_k \leq OPT$  (by observation 2)
  - 2  $A \leq OPT$ . Why?
    - Consider the state when the job  $k$  was assigned to  $M_i$ . At that time,  $M_i$  had a total load of  $A$ , which is the smallest load of all machines (by the greedy rule of the algorithm).
    - Formally,  $A \leq \frac{1}{m}(\sum_{j=1}^n t_j - t_k) \leq \frac{1}{m} \sum_{j=1}^n t_j \leq OPT$  (by key observation 1).

Question: is this an accurate analysis?

# A tight example of GREEDYMAKESPAN1 algorithm

- Consider a special instance: a total of  $n = m(m-1) + 1$  jobs with loads  $t_1 = t_2 = \dots = t_{n-1} = 1$ , and  $t_n = m$ .

GreedyMakeSpan1  
returns  $T = 2m - 1$

$OPT = m$

- GREEDYMAKESPAN1:  $T = 2m - 1$  (if the largest job  $n$  is processed at the last step).
- OPT:  $OPT = m$ .
- Thus, approximation factor is:  $\alpha = \frac{T}{OPT} = 2 - \frac{1}{m}$ .  $\alpha$  can be arbitrarily close to 2 when  $m$  increases.

## Another greedy algorithm for MAKESPAN

# Basic idea

- Basic idea: The tight example for GREEDYMAKESPANALGO1 algorithm implies that it is not wise to process the largest job finally. In other words, it might be a good idea to process large jobs first.

# Another greedy algorithm

## GREEDYMAKESPAN2 algorithm

- 1: **for**  $i = 1$  to  $m$  **do**
- 2:    $T_i = 0$ ; //assigning all machines with 0 jobs;
- 3:    $A_i = \text{NULL}$ ;
- 4: **end for**
- 5: **sort jobs in decreasing order of**  $t_j$ ; //process large jobs first
- 6: **for**  $j = 1$  to  $m$  **do**
- 7:   Let  $k = \text{argmin } T_i$ ; //assign job  $j$  to  $M_k$ ;
- 8:    $A_k = A_k \cup \{j\}$ ;
- 9:    $T_k = T_k + t_j$ ;
- 10: **end for**

- Key observation 3:**  $OPT \geq 2t_j$  for any  $j \geq m+1$  if all jobs were sorted decreasingly.  
 (Why? Consider the first  $m+1$  jobs only. At least two jobs should be assigned to a machine. Thus,  $OPT \geq 2t_{m+1}$ .)

## Theorem

$T \leq 1.5OPT$ , i.e, GREEDYMAKESPANALGO2 is a 1.5-approximation algorithm.

## Proof.

- Let  $M_i$  be the machine with the heaviest load  $T$  reported by GREEDYMAKESPANALGO2 algorithm;
- Divide  $T$  into two parts: the last job  $k$ , and the previous jobs. Thus  $T = t_k + A$ , where  $A$  denotes the total load of the previous jobs.
- $T \leq 1.5OPT$  since:
  - ①  $t_k \leq \frac{1}{2}OPT$  (by observation 3)
  - ②  $A \leq OPT$  (the same argument to the last theorem)

## The key steps in approximation algorithm design

- We are facing a dilemma:
  - 1 In order to establish the approximation guarantee, we should compare the quality of a solution against the quality of the optimal solution  $OPT$ .
  - 2 However, it is NP-Hard to compute the optimal solution value  $OPT$  and to find an optimal solution.
- Question: How can we establish the connection with  $OPT$  **without** the exact value of  $OPT$ ?
- The answer to this question provides a key step in the design of approximation algorithms.

## The key step in approximation algorithm cont'd

- **Strategy:** Finding a lower bound of  $OPT$  and **comparing a solution with the lower bound** rather than **comparing with  $OPT$  directly!**
- **Key step 1:** Although it is NP-Hard to find optimal solution, it might be polynomial-time computable to find a **“tight lower bound”** of  $OPT$ .
- **Key step 2:** We should figure out a process to yield a feasible solution, and compare this solution with the lower bound of  $OPT$ .

# Finding a lower bound

- Then how to find a lower bound of  $OPT$ ?
  - 1 Combinatorial ways: problem specific and thus cohesive; then we design greedy or DP algorithm;
  - 2 LP-based method as a united way: LP-relaxation, duality, etc.

Another example: SET COVER problem

- Practical problems:
  - An anti-virus package identifies a viruses based on characteristic “keywords” set, and a keyword corresponds to several viruses. The question is how to select a small “representative” keywords set to detect all viruses.
  - To form a committee, containing as few people as possible, to cover all requisite skills;

# SET COVER problem: formulation

## Formalized Definition:

**INPUT:** a set of  $n$  elements  $U = \{1, 2, \dots, n\}$ , and  $m$  subsets of  $U$ , denoted as  $S_1, S_2, \dots, S_m$ . Each subset  $S_i$  has a weight  $w_i$ .

**OUTPUT:** to find a collection of subsets, with the minimal weight sum, such that all elements of  $U$  are covered.

Note: SETCOVER problem plays an important role in approximation algorithm design as MATCHING problem in the design of exact algorithm.

# An example

- Question: how to choose several subsets, with the minimal weight sum, such that all elements are covered?

- **Key observation:** solution is a collection of subsets. Imagine the solving process as a series of decisions. At each decision step, we decide to choose a subset or abandon it.
- **Greedy selection rule:** we should consider two aspects of a subset:
  - 1 the smaller the weight, the better;
  - 2 the more items it covers, the better.

Thus, it is reasonable to select a subset based on “**the ratio of weight over the number of items it covers**”.

## GREEDY-SET-COVER algorithm

- 1:  $I = \text{NULL}$ ; //  $I$  denotes the index of selected subsets;
- 2:  $R = U$ ; //  $R$  denotes the remaining elements;
- 3: **while**  $R \neq \text{NULL}$  **do**
- 4:    $j = \arg \min_i \frac{w_i}{|S_i \cap R|}$ ;
- 5:   **Let**  $p_j = \frac{w_j}{|S_j \cap R|}$ ;
- 6:   **for all** remaining element  $e \in R \cap S_j$  **do**
- 7:     **Set**  $\text{price}(e) = p_j$ ;
- 8:   **end for**
- 9:    $I = I \cup \{j\}$ ;
- 10:    $R = R - S_j$ ;
- 11: **end while**

# An example: Step 1

Step 1:

- $R = U = \{1, 2, 3, 4, 5, 6, 7, 8\}$ ;
- $p_1 = \frac{w_1}{|S_1 \cap R|} = \frac{6}{4}$ ;  $p_2 = \frac{w_2}{|S_2 \cap R|} = \frac{2}{2}$ ;  $p_3 = \frac{w_3}{|S_3 \cap R|} = \frac{7}{4}$ ;  
 $p_4 = \frac{w_4}{|S_4 \cap R|} = \frac{3}{5}$ ;  $p_5 = \frac{w_5}{|S_5 \cap R|} = \frac{4}{2}$ ;
- Choose  $S_4$  since  $p_4$  is the smallest one.

# An example: Step 2

Step 2:

- $R = \{1, 3, 7\}$ ;
- $p_1 = \frac{w_1}{|S_1 \cap R|} = \frac{6}{2}$ ;  $p_2 = \frac{w_2}{|S_2 \cap R|} = \frac{2}{1}$ ;  $p_3 = \frac{w_3}{|S_3 \cap R|} = \frac{7}{3}$ ;
- $p_5 = \frac{w_5}{|S_5 \cap R|} = \frac{4}{1}$ ;
- Choose  $S_2$  since  $p_2$  is the smallest one.

# An example: Step 3

Step 3:

- $R = \{1, 3\}$ ;
- $p_1 = \frac{w_1}{|S_1 \cap R|} = \frac{6}{2}$ ;  $p_3 = \frac{w_3}{|S_3 \cap R|} = \frac{7}{2}$ ;
- Choose  $S_1$  since  $p_1$  is the smallest one.

# An example: Step 4

Step 4:

- $R = \{\}$ . Done!
- Solution: We select  $I = \{S_1, S_2, S_4\}$  with the sum of weight: 11.
- Optimal solution: selecting  $\{S_3, S_4\}$  with the sum of weight: 10.

- We will prove the following theorem:

## Theorem

*GREEDY-SET-COVER algorithm is an  $H(f)$ -approximation algorithm, where  $f = \max_i |S_i|$ .*

- Meaning: The algorithm returns a subset  $I = \{S_1, S_2, S_4\}$  with the total weight of 11. We guarantee that  $W = 11 \leq H(5)OPT = H(5)10$ .

## Proof.

Let  $S^*$  be the optimal solution, and  $S$  be the solution returned by GREEDY-SET-COVER algorithm. We have:

$$\sum_{S_i \in S} w_i = \sum_{e \in U} \text{price}(e) \quad (\text{by Line 7-9}) \quad (1)$$

$$\leq \sum_{S_j \in S^*} \sum_{e \in S_j} \text{price}(e) \quad (\text{by } S^* \text{ covers } U) \quad (2)$$

$$\leq \sum_{S_j \in S^*} H(|S_j|) w_j \quad (\text{by the lemma}) \quad (3)$$

$$\leq \sum_{S_j \in S^*} H(f) w_j \quad (d \text{ is the largest}) \quad (4)$$

$$= H(f) OPT \quad (5)$$

# Finding a lower bound

## Lemma

For each subset  $S_i$ ,  $\sum_{e \in S_i} \text{price}(e) \leq H(|S_i|)w_i$ .

- Take  $S_1$  as an example. We have:

$$\sum_{e \in S_1} \text{price}(e) = \left(\frac{w_4}{5} + \frac{w_4}{5}\right) + \left(\frac{w_1}{2} + \frac{w_1}{2}\right) \quad (6)$$

$$\leq \left(\frac{w_1}{4} + \frac{w_1}{4}\right) + \left(\frac{w_1}{2} + \frac{w_1}{2}\right) \quad (7)$$

$$\leq \left(\frac{w_1}{4} + \frac{w_1}{3}\right) + \left(\frac{w_1}{2} + \frac{w_1}{1}\right) \quad (8)$$
$$= w_1 H(4)$$

- Here, the first  $\leq$  is due to the selecting criteria in Step 2, i.e.  $p_4 = \frac{w_4}{5}$  is smaller than  $p_1 = \frac{w_1}{4}$ , and the selecting criteria in Step 3, i.e.  $p_1 = \frac{w_1}{2}$  is smaller than  $p_3 = \frac{w_3}{2}$ .

Question: is this an accurate analysis?

# A tight example

- Consider a special instance:  $n + 1$  subsets with weights  $\frac{1}{n}, \frac{1}{n-1}, \dots, \frac{1}{2}, 1$  and  $1 + \epsilon$ , respectively.

- Optimal solution: selecting only one subset with weight  $1 + \epsilon$ ;
- GREEDY-SET-COVER result: selecting  $n$  subsets with the sum of weight  $\frac{1}{n} + \frac{1}{n-1} + \dots + \frac{1}{2} + 1 = H(n)$ .

LP as a unified approach framework to lower bound  $OPT$

Lower bound 1:  $z_{LP} \leq z_{ILP} = OPT$

# LP as a unified framework: Step 1

- **Step 1:** Formulate the problem as an integer linear program (ILP);
- We define a 0/1 variable  $x_j$  for each subset  $S_j$ , where  $x_j = 1$  means the selection of  $S_j$ , and 0 means abandon.
- ILP model:

$$\begin{array}{ll} \min & z = \sum_{j=1}^m w_j x_j \\ \text{s.t.} & \sum_{j: e \in S_j} x_j \geq 1 \quad \forall e \in U \\ & \textcolor{red}{x_j} = \textcolor{red}{0/1} \quad \forall i \end{array}$$

- Thus we have  $OPT = z_{ILP}$ , where  $z_{ILP}$  denotes the optimal objective value of the ILP model.

# LP as a unified approach framework: Step 2

- **Step 2:** Relaxing ILP into LP;
- LP relaxation:

$$\begin{array}{ll} \min & z = \sum_{j=1}^m w_j x_j \\ \text{s.t.} & \sum_{j: e \in s_j} x_j \geq 1 \quad \forall e \in U \\ & x_j \geq 0 \quad \forall i \\ & x_j \leq 1 \quad \forall i \end{array}$$

- **Key observation 1:**  $z_{LP} \leq z_{ILP} = OPT$ , where  $z_{LP}$  denotes the optimal objective value of the LP model.

# LP as a unified approach framework: Step 3

- **Step 3:** Since the LP model might generate a fractional solution, a clever way should be figured out to transform the **optimal solution to LP** (in polynomial-time) to a **feasible solution to ILP**, whose objective value is close to **the optimal LP objective value**.
- The final difficulty: how to obtain a feasible solution to ILP based on the optimal solution to LP? **Rounding!**

# Algorithm1: LP+Rounding

## LP+Rounding algorithm

- 1: Solve the linear program  $LP$  to get an optimal solution  $x^*$ ;
- 2:  $I = \text{NULL}$ ;
- 3: **for all** subset  $S_j$  **do**
- 4:   **if**  $x_j^* \geq \frac{1}{f}$  **then**
- 5:      $I = I + \{j\}$ ;
- 6:   **end if**
- 7: **end for**
- 8: **return**  $I$ ;

- Here  $d$  denotes the largest coverage of any element in  $U$ , i.e.  
$$d = \max_{e \in U} |\{j : e \in S_j\}|.$$

# An example

$$\begin{array}{llllllllll}
 \min & 6x_1 & + & 2x_2 & + & 7x_3 & + & 3x_4 & + & 4x_5 & & \\
 s.t. & x_1 & & & + & x_3 & & & & & \geq 1 & \text{(item 1,3)} \\
 & x_1 & & & & & + & x_4 & & & \geq 1 & \text{(item 2,4)} \\
 & & & & & x_3 & + & x_4 & & & \geq 1 & \text{(item 5)} \\
 & & x_2 & & & & & & + & x_5 & \geq 1 & \text{(item 6)} \\
 & & x_2 & + & x_3 & & & & & + & x_5 & \geq 1 & \text{(item 7)} \\
 & & x_2 & & & & + & x_4 & & & \geq 1 & \text{(item 8)} \\
 & & & & & & & & & x_i & \geq 0 & \\
 & & & & & & & & & x_i & \leq 1 & 
 \end{array}$$

- LP optimal solution:  $x_1 = 0.5$ ;  $x_2 = 1$ ;  $x_3 = 0.5$ ;  $x_4 = 0.5$ ;  $x_5 = 0$ ;
- Objective value of LP: 10. ( $z_{LP} \leq z_{ILP} = OPT$ .)
- Rounding solution:  $x'_1 = 1$ ;  $x'_2 = 1$ ;  $x'_3 = 1$ ;  $x'_4 = 1$ ;  $x'_5 = 0$ ;
- Objective value:  $18 \leq d \times z_{LP}$ .

# Correctness of Algorithm1

## Theorem

*Algorithm1 yields a set cover.*

## Proof.

(by contradiction)

- Suppose there is an element  $e$  not covered, i.e.  $e \notin \cup_{j \in I} S_j$ .
- Then for each  $S_j$  that contains  $e$  as a member, we have  $x_j^* < \frac{1}{f}$ ; (Otherwise,  $S_j$  should be selected by Algorithm1.)
- Thus,  $\sum_{j: e \in S_j} x_j^* < \frac{1}{d} |\{j : i \in S_j\}| \leq 1$ .
- A contradiction against the linear program constraints.

# Analysis of Algorithm1

## Theorem

(Hochbaum '82) *Algorithm1* is an  $f$ -approximation algorithm for SETCOVER.

## Proof.

- Algorithm1 returns a collection  $I$  with cost:  $C = \sum_{j \in I} w_j$

$$\begin{aligned} C &= \sum_{j \in I} w_j \\ &\leq \sum_{j \in I} w_j x_j^* d \\ &\leq \sum_{j=1}^m w_j x_j^* d \\ &= d \sum_{j=1}^m w_j x_j^* \\ &= dz_{LP} \\ &\leq fOPT \end{aligned}$$

- Here, the first inequality follows due to the “rounding criteria”, i.e.  $x_j^* \geq \frac{1}{d}$ .

Lower bound 2:  $z_{Dual} \leq z_{LP} \leq z_{ILP} = OPT$

# Algorithm2: Dual LP + Rounding

- Basic idea: rounding the dual solution.
- Dual:

$$\begin{array}{ll} \max d = & \sum_{e \in U} y_e \\ \text{s.t.} & \sum_{e: e \in S_j} y_e \leq w_j \quad \forall S_j \\ & y_e \geq 0 \quad \forall e \in U \end{array}$$

# Dual provides another lower bound

**Key observation 2:**  $\sum_e y_e \leq z_{LP} \leq OPT$  for any feasible dual solution  $y$ ;

# Algorithm2: Dual LP + Rounding

## Dual LP + Rounding Algorithm

- 1: Solve the dual  $LP$  to get an optimal solution  $y^*$ ;
- 2:  $I = \text{NULL}$ ;
- 3: **for all** subset  $S_j$  **do**
- 4:   **if**  $\sum_{e: e \in S_j} y_e^* = w_j$  **then**
- 5:      $I = I + \{j\}$ ;
- 6:   **end if**
- 7: **end for**
- 8: **return**  $I$ ;

# An example

$$\begin{array}{rcll}
 \max & y_1 & + & y_2 & + & y_3 & + & y_4 & + & y_5 & + & y_6 & + & y_7 & + & y_8 & & \\
 s.t. & y_1 & + & y_2 & + & y_3 & + & y_4 & & & & & & & & & & \leq 6 \\
 & & & y_2 & & & & & & & & & & y_7 & + & y_8 & & \leq 2 \\
 & y_1 & & & + & y_3 & & & + & y_5 & & & & + & y_7 & & & \leq 7 \\
 & & & y_2 & & & + & y_4 & + & y_5 & & & & & & + & y_8 & \leq 3 \\
 & & & & & & & & & & & y_6 & + & y_7 & & & & \leq 4 \\
 & & & & & & & & & & & & & & & & y_i & \geq 0
 \end{array}$$

- Dual LP optimal solution:  $y_1 = 6$ ;  $y_2 = 0$ ;  $y_3 = 0$ ;  $y_4 = 0$ ;  $y_5 = 0$ ;  $y_6 = 3$ ;  $y_7 = 1$ ;  $y_8 = 0$ ;
- Objective value of Dual: 10 ( $z_{DualLP} \leq z_{LP} \leq z_{ILP} = OPT.$ )
- Tight constraints:  $I = \{1, 3, 4, 5\}$ ;
- Objective value:  $20 \leq d * z_{DualLP}.$

# Correctness of Algorithm2

## Theorem

*Algorithm2 yields a set cover.*

## Proof.

(by contradiction again)

- Suppose there is an element  $\hat{e}$  that is not covered by the selected subsets in  $I$ ;
- Then for ALL  $S_j$  containing  $\hat{e}$ , we have  $\sum_{e: e \in S_j} y_e^* < w_j$ ;  
(Otherwise, a  $S_j$  should be selected and thus  $e$  will be covered.)
- Thus, increasing  $y_{\hat{e}}^*$  (by a small positive amount) will increase the objective function value of dual LP without violating the constraints. A contradiction with the optimality of  $y^*$ .

# Analysis of Algorithm2

## Theorem

*Algorithm2 is a  $d$ -approximation algorithm.*

## Proof.

Let  $C$  denote the sum weight of the subsets that Algorithm2 returns, i.e.  $C = \sum_{j \in I} w_j$ . We have:

$$\begin{aligned} C &= \sum_{j \in I} w_j \\ &= \sum_{j \in I} \sum_{e: e \in S_j} y_e^* \\ &\leq d \sum_{e: e \in U} y_e^* \quad (\text{since any } e \text{ was included at most } d \text{ times}) \\ &= dz_{Dual \text{ LP}} \\ &\leq dOPT \quad (\text{since } z_{Dual \text{ LP}} \leq z_{LP} \leq z_{ILP}) \end{aligned}$$

Lower bound 3:

*value of any dual feasible solution*  $\leq z_{Dual} \leq z_{LP} \leq z_{ILP} = OPT$

# Algorithm3: Primal\_dual + Rounding

- Basic idea: a feasible dual solution is enough for lower bounding  $OPT$ . Thus, we can employ primal\_dual strategy to construct a feasible dual solution rather than solving Dual LP to get an optimal dual solution.

# Algorithm3: Primal\_dual + Rounding

## Primal\_Dual + Rounding Algorithm3

```
1:  $I = \text{NULL}$ ;  
2:  $y_e = 0$  for all  $e \in U$ ;  
3: while exists an element  $\hat{e}$  not covered do  
4:   for all subset  $S_j$  containing  $\hat{e}$  do  
5:      $g_j = w_j - \sum_{e: e \in S_j} y_e$ ; // calculate the gap of constraint  $j$ ;  
6:   end for  
7:    $i = \arg \min_j g_j$ ;  
8:    $y_{\hat{e}} = y_{\hat{e}} + g_i$ ;  
9:    $I = I \cup \{i\}$ ;  
10: end while  
11: return  $I$ ;
```

## An example: Step 1

- Initially, we have  $y_i = 0$  for all  $1 \leq i \leq 8$ .
- Consider element  $y_2$ . There are two constraints  $S_1$  and  $S_4$ .
- We increase  $y_2$  to 3 (selecting  $S_4$ ).

## An example: Step 2

- Consider element  $y_1$ . There are two constraints  $S_1$  and  $S_3$ .
- We increase  $y_1$  to 3 (selecting  $S_1$ ).

## An example: Step 3

- Consider element  $y_7$ . There are three constraints  $S_2, S_3$  and  $S_5$ .
- We increase  $y_7$  to 2 (selecting  $S_2$ ).

# An example: Step 4

- All elements have been covered. Done!
- Dual solution:  
 $y_1 = 3; y_2 = 3; y_7 = 2; y_3 = y_4 = y_5 = y_6 = y_8 = 0;$
- Dual objective value: 8. (Dual feasible solution,  
 $z \leq z_{Dual} \leq z_{LP} \leq z_{ILP} = OPT$ )
- Tight constraints:  $I = \{S_4, S_1, S_2\}$
- Objective value:  $11 \leq d \times z \leq d \times z_{Dual} \leq d \times OPT$

## Lemma

*Algorithm3 yields a dual feasible solution  $y$ , and  $\sum_{e:e \in S_j} y_e = w_j$  for any  $j \in I$ .*

## Proof.

- Base case:  $y = 0$  is dual feasible since  $\sum_{e:e \in S_j} y_e = 0 \leq w_j$ ;
- Induction: assuming that  $y$  is dual feasible before an iteration of while loop, i.e.  $\sum_{e:e \in S_j} y_e \leq w_j$ . Suppose we increase  $y_{\hat{e}}$  by  $g_i$  to generate a new solution  $y'$ . We will show that  $y'$  is also a dual feasible solution.

$$\begin{aligned}\sum_{e:e \in S_j} \hat{y}'_e &= \sum_{e:e \in S_j} y_e + g_i \quad (g_i \text{ is minimal}) \\ &= \sum_{e:e \in S_j} y_e + (w_i - \sum_{e:e \in S_i} y_e) \\ &\leq \sum_{e:e \in S_j} y_e + (w_j - \sum_{e:e \in S_j} y_e) \\ &= w_j\end{aligned}$$

## Theorem

*(Bar-Yehuda, Even '81) Algorithm3 is a  $d$ -approximation algorithm.*

## Proof.

Let  $C$  denote the sum weight of subsets generated by Algorithm2, i.e.  $C = \sum_{j \in I} w_j$ . We have:

$$\begin{aligned} C &= \sum_{j \in I} w_j \\ &= \sum_{j \in I} \sum_{e: e \in S_j} y_e \quad (\text{by lines 9-10}) \\ &\leq d \sum_{e: e \in U} y_e \quad (e \text{ is covered at most } d \text{ times}) \\ &\leq dz_{Dual} \quad (y \text{ is a dual feasible solution}) \\ &\leq dOPT \quad (\text{since } y \text{ is only a dual feasible solution}) \end{aligned}$$

Another example of rounding: the generalization of MAKESPAN problem

# The generalization of MAKESPAN problem

Practical problem: We have multiple servers to process a set of jobs. **However, some machines cannot be assigned to a job.** How to schedule jobs to machines as “balanced” as possible?

**INPUT:**

$m$  servers  $M_1, M_2, \dots, M_m$ ,  $n$  jobs  $J = \{1, \dots, n\}$  (each job  $j$  has a processing time  $t_j$ ). Each job  $j$  has a subset of machines  $S_j \subset \{M_1, \dots, M_m\}$  that it can use.

**OUTPUT:**

An assignment of jobs to machines to minimize the *makespan*, i.e. the maximum load on any machine,  $T = \max_i \sum_{j \in A(i)} t_j$ , where  $A(i)$  denotes the jobs assigned to machine  $i$ ;

(ILP)

$$\begin{array}{llll} \min & L \\ \text{s.t.} & \sum_{i=1}^m x_{ji} = t_j & \text{for all } j \in J \\ & \sum_{j=1}^n x_{ji} \leq L & \text{for all } i \\ & x_{ji} = 0/t_j & \text{for all } j \in J, i \in S_j \\ & x_{ji} = 0 & \text{for all } j \in J, i \notin S_j \end{array}$$

(Intuition:  $x_{ji}$  indicates how much of the load of  $t_j$  is assigned to machine  $M_i$  )

(LP)

$$\begin{array}{ll} \min & L \\ \text{s.t.} & \sum_{i=1}^m x_{ji} = t_j \quad \text{for all } j \in J \\ & \sum_{j=1}^n x_{ji} \leq L \quad \text{for all } i \\ & x_{ji} \leq t_j \quad \text{for all } j \in J, i \in S_j \\ & x_{ji} \geq 0 \quad \text{for all } j \in J, i \in S_j \\ & x_{ji} = 0 \quad \text{for all } j \in J, i \notin S_j \end{array}$$

- **Key observation 1:**  $z_{LP} \leq z_{ILP} = OPT$
- **Key observation 2:**  $\max_j t_j \leq OPT$

# An example

(LP)

$$\begin{array}{llllll} \min z = & L \\ \text{s.t.} & & x_{12} & + x_{13} & = & 6 \\ & x_{21} & + x_{22} & + x_{23} & = & 9 \\ & x_{31} & + x_{32} & + x_{33} & = & 15 \\ & & x_{21} & + x_{31} & \leq & L \\ & x_{12} & + x_{22} & + x_{32} & \leq & L \\ & x_{13} & + x_{23} & + x_{33} & \leq & L \\ & & & x_{ji} & \geq & 0 \end{array}$$

# How to construct a valid schedule from LP solution?

- Suppose we have already obtained a solution to the LP. The final question is: how to construct a valid schedule from the LP solution?

# How to construct a valid schedule from LP solution?

- Recall that for any job  $j$ , we have  $t_j = x_{j1} + x_{j2} + \dots + x_{jm}$ . There are two possible cases:
  - $\exists i, x_{ji} = t_j$  (called “integral job”): Intuitively, job  $j$  was scheduled to machine  $M_i$  as a whole, e.g. job 1.
  - $\forall i, x_{ji} < t_j$  (called “fractional job”): Intuitively, job  $j$  was decomposed into parts, which were distributed to different machines, e.g., two parts of job 2 was distributed to  $M_1$  and  $M_2$ .
- The difficulty is how to deal with fractional jobs.

# Two possibilities of the fractional jobs

- Let's focus on the fractional jobs via:
  - Removing the "integer jobs";
  - Removing the **unused assignments**, i.e.  $x_{ji} = 0$ ;
- There are two possibilities:
  - 1 The assignment contains **no cycle**;
  - 2 The assignment contains **one or more cycles**;

## Case 1: the assignment contains no cycle

- In this case, a valid schedule can be constructed via the following rounding strategy:
  - ① Rounding: If a part of a fractional job  $j$  was scheduled to machine  $M_i$ , we can simply schedule the whole job  $j$  to  $M_i$ .
  - ② Restriction: Each machine receives **at most** one fractional job.

# Implementing rounding

- The rounding operation is feasible since:
  - 1 “No cycle” means a tree rooted at a job.
  - 2 Notice that any leaf should be a “machine” rather than a “job” (Reason: a “leaf job” is connected with its parent only; thus it should be an “integer job”)
  - 3 So we can simply assign a fractional job **completely** to an **arbitrary** child, say assign  $J_2$  to  $M_1$ , and assign  $J_3$  to  $M_2$ .
- Time complexity:  $O(mn)$ .

## Case 1: the assignment contains no cycle cont'd

- Combining the "integer jobs", we will have the following schedule:
- $J_{M1} = \{2\}; J_{M2} = \{1\}; J_{M3} = \{3\}$ .

- $\text{MakeSpan} = 15 \leq 2 \times z_{LP} = 20$
- We can show that the rounding strategy won't introduce too many load to any machine.

## Theorem

*MakeSpanApprox* is a 2-approximation algorithm.

## Proof.

- Let  $T$  denotes the makespan that *MakeSpanApprox* yields, and  $T$  is obtained from machine  $M_i$ .
- Let  $J_i$  denote the jobs assigned to  $M_i$ .  $J_i$  consists of two parts: integral jobs assigned to machine  $i$  ( $x_{ij} = t_j$ ), and at most **one** fractional job (denoted as  $f_i$ ) that is assigned to multiple machines ( $x_{ij} < t_j$ ). We have:

$$T = \sum_{j \in J_i} t_j \quad (9)$$

$$= \sum_{j \in J_i, j \neq f_i} t_j + t_{f_i} \quad (10)$$

$$= \sum_{j \in J_i, j \neq f_i} x_{ij} + t_{f_i} \quad (\text{by the definition of integral jobs}) \quad (11)$$

$$\leq \sum_{j \in J_i} x_{ij} + t_{f_i} \quad (12)$$

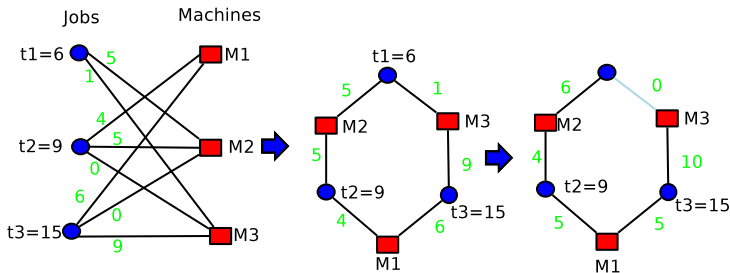

$$\leq z_{LP} + t_{f_i} \quad (13)$$

$$\leq z_{LP} + OPT \quad (\text{by key observation 2}) \quad (14)$$

$$\leq 2OPT \quad (\text{by key observation 1}) \quad (15)$$

## Case 2: the assignment contains cycles

- In fact, any cycle can be eliminated without load changes for any machine using the following **“augmentation”** operation:
  - 1 Consider a cycle  $C$ . We first find the smallest load (denoted as  $\delta$ );
  - 2 Increasing/decreasing loads by  $\delta$  on edges in the cycle;
  - 3 Thus the cycle will be eliminated without no influence on the loads. For example, edge  $J_1 - M_3$  is cut to break the cycle.
- Time complexity:  $O(|C|)$  for cycle  $C$ . The operation will be repeated at most  $O(mn)$  times to remove all cycles.

## MAKESPANAPPROX Algorithm

- 1: Solving the LP model to get solution  $x_{ij}$ ;
- 2: Removing cycles in the schedule graph via **augmentation**;
- 3: **for**  $i = 1$  to  $m$  **do**
- 4:   assigning integral job  $j$  to  $i$  if  $x_{ij} = t_j$ ;
- 5:   assigning at most **one** fractional job to  $i$ ;
- 6: **end for**

Other useful technique: scaling and parametric pruning

- Scaling: rounding a real number to an integer; grid;
- Parametric pruning: Suppose we have already known  $OPT$ , we might be able to prune away irrelevant parts of the input and thereby simplify the search for a good solution.

Scaling technique: from pseudo polynomial time algorithm to PTAS

# KNAPSACK problem

Given a set of items, each item has a weight and a value, to determine a set of items such that the total weight is less than a given limit and the total value is as large as possible.

## Formalized Definition:

- **Input:**  
a set of items. Item  $i$  has weight  $w_i$  and value  $v_i$ , and a total weight limit  $W$ ;
- **Output:**  
the set of items which maximize the total value with total weight below  $W$

# A Knapsack instance

What's the best solution?

# A Knapsack instance

Greedy solution:

Note: there are two types of dynamic programming algorithms to solve KNAPSACK problem.

# Dynamic programming algorithm 1

- Imagine the solving process as a series of decisions.
- Suppose we have already obtained the optimal solution  $S$ . Let's consider the first decision step, we have two options: select item  $n$ , or abandon it.
- Thus the general form of sub-problems can be set as: to calculate the maximum value of any solution using a subset of the items  $\{1, 2, \dots, i\}$  and a bag of size  $w$ , denoted as  $OPT(i, w)$ .
- Our objective:  $OPT(n, W)$ .
- Optimal sub-structure:  
$$OPT(n, W) = \max\{OPT(n-1, W), OPT(n-1, W-w_n) + v_n\};$$

## Knapsack DP1

```
1: for  $w = 1$  to  $W$  do  
2:    $M[0, w] = 0$ ;  
3: end for  
4: for  $i = 1$  to  $n$  do  
5:   for  $w = 1$  to  $W$  do  
6:      $M[i, w] = \max\{M[i-1, w], w_i + M[i-1, w - w_i]\}$ ;  
7:   end for  
8: end for  
9: return  $M[n, W]$ ;
```

Time complexity:  $O(nW)$ . Pseudo polynomial time.

# A dual problem

**INPUT:** a set of  $n$  items. An item  $i$  has weight  $w_i$  and value  $v_i$ .  
The value requirement  $V$ ;  
**OUTPUT:** to select a subset of items to minimise the total weight with value at least  $V$ ;

Note: if this problem was solved, the Knapsack problem can be solved by by **finding the largest value  $V$  such that**  
 **$OPT(n, V) \leq W$ .**

# Dynamic programming algorithm 2

- Imagine the solving process as a series of decisions.
- Suppose we have already obtained the optimal solution  $S$ .  
Let's consider the first decision step, there are two possibilities: select item  $n$  or abandon it;
- The general form of sub-problems: to calculate the smallest bag size, i.e. the bag can hold a subset of items  $\{1, 2, \dots, i\}$  with value at least  $V$  (denoted as  $OPT(i, V)$ );
- Our objective: the largest  $V$  such that  $OPT(n, V) \leq W$ .  
(Notice that  $V \leq nv^*$ , where  $v^* = \max_i \{v_i\}$ );
- Optimal sub-structure:

$$OPT(n, V) = \min \begin{cases} OPT(n-1, V) & \text{abandon item } n \\ w_n & \text{select item } n \text{ only} \\ w_n + OPT(n-1, V - v_n) & \text{otherwise} \end{cases}$$

## Knapsack DP2

```
1: for  $i = 0$  to  $n$  do
2:    $M[i, 0] = 0$ ;
3: end for
4: for  $i = 1$  to  $n$  do
5:   for  $V = 1$  to  $\sum_{k=1}^i v_k$  do
6:     if  $V > \sum_{k=1}^{i-1} v_k$  then
7:        $M[i, V] = w_i + M[i-1, V - v_i]$ ;
8:     else
9:        $M[i, V] = \min\{M[i-1, V], w_i + M[n-1, v - v_i]\}$ ;
10:    end if
11:  end for
12: end for
```

Time complexity:  $O(n^2 v^*)$ . Still pseudo-polynomial time.

# Converting pseudo-polynomial time algorithm to PTAS

- Basic idea: the algorithm is good when  $v^*$  is small. But how to deal with the case when  $v^*$  is large? **Scaling!**
- More specifically, a large  $v_i$  can be scaled to a smaller  $\hat{v}_i = \lceil \frac{v_i}{b} \rceil$ . We denote  $\bar{v}_i = \hat{v}_i b$ ;

		Rounding $b = 1000$		Equivalent	
V1	3278		$\bar{V1}$ 4000		$\hat{V1}$ 4
V2	1956		$\bar{V2}$ 2000		$\hat{V2}$ 2
V3	4123		$\bar{V3}$ 5000		$\hat{V3}$ 5
V4	2233		$\bar{V4}$ 3000		$\hat{V4}$ 3

Knapsack-Approx( $\epsilon$ )

- 1: Let  $v^* = \max_i v_i$ ;
- 2: Let  $b = \frac{\epsilon}{n} v^*$ ;
- 3: Calculate  $\hat{v}_i = \lceil \frac{v_i}{b} \rceil$  for each item  $i$ ;
- 4: Run KnapsackDP2 on the items with value  $\hat{v}_i$  and return the optimal solution  $S$ ;

Knapsack-Approx algorithm runs in polynomial time.

In fact, the running time is  $O(n^2 \hat{v}^*) = O(n^2 \frac{v^*}{b}) = O(\frac{n^3}{\epsilon})$ .

## Theorem

Let  $S$  be the solution yielded by Knapsack-Approx algorithm, and  $S^*$  be any feasible solution such that  $\sum_{i \in S^*} w_i \leq W$ . We will show that  $\sum_{i \in S} v_i \geq \frac{1}{1+\epsilon} \sum_{i \in S^*} v_i$ .

## Proof.

$$\sum_{i \in S^*} v_i \leq \sum_{i \in S^*} \bar{v}_i \quad (\text{by } v_i \leq \bar{v}_i) \quad (16)$$

$$\leq \sum_{i \in S} \bar{v}_i \quad (S \text{ is optimal solution}) \quad (17)$$

$$\leq \sum_{i \in S} (v_i + b) \quad (\text{by } \bar{v}_i \leq v_i + b) \quad (18)$$

$$\leq nb + \sum_{i \in S} v_i \quad (19)$$

$$\leq (1 + \epsilon) \sum_{i \in S} v_i \quad (\text{since } nb \leq \epsilon \sum_{i \in S} v_i) \quad (20)$$

# Why $b$ was set to $b = \frac{\epsilon}{n} v^*$ ?

Note:  $b$  is set to  $b = \frac{\epsilon}{n} v^*$  according to two sides of considerations:

- 1 Time-complexity:  $O(n^2 \frac{v^*}{b})$  is polynomial in  $n$  and  $\frac{1}{\epsilon}$ .
- 2 Approximation ratio:  $nb \leq \epsilon \sum_{i \in S} v_i$ .

## Parametric pruning

The algorithm consists of three steps:

- 1 Pruning: Suppose we have a guess of  $OPT$ , denoted as parameter  $t$ . For each given  $t$ , the input instance will be pruned by removing the parts that will not be used in any solution with cost  $> t$ . Denote the pruned instance as  $I(t)$ .
- 2 Lower bound: the family of  $I(t)$  is used for computing a lower bound of  $OPT$ , say  $t^*$ ;
- 3 Good solution: a solution is found in instance  $I(\alpha t^*)$  for a suitable choice of  $\alpha$ .

# Parameter pruning for K-CENTER problem

(See extra slides)

## Appendix: PARTITION is NP-Complete

- PARTITION problem is to decide whether a given multiset of integers can be partitioned into two "halves" that have the same sum.
- More precisely, given a multiset  $S$  of integers, is there a way to partition  $S$  into two subsets  $S_1$  and  $S_2$  such that the sum of the numbers in  $S_1$  equals the sum of the numbers in  $S_2$ ?
- PARTITION problem can be easily proved to be NP-complete via a reduction from SUBSETSUM problem.
