

CS711008Z Algorithm Design and Analysis

Lecture 1. Introduction and some representative problems

Dongbo Bu

Institute of Computing Technology
Chinese Academy of Sciences, Beijing, China

The origin of the word “Algorithm”

Figure 1: Muhammad ibn Musa al-Khwarizmi (C. 780—850), a Persian scholar, formerly Latinized as Algoritmi

- In the twelfth century, Latin translations of his work on the Indian-Arabic numerals introduced the decimal positional number system to the Western world.

- Al-Khwarizmi's *The Compendious Book on Calculation by Completion and Balancing* presented the first systematic solution of **linear** and **quadratic equations** in Arabic.
- Two words:
 - **Algebra**: from Arabic "al-jabr" meaning "reunion of broken parts" — one of the two operations he used to solve equations
 - **Algorithm**: a step-by-step set of operations to get solution to a problem

Algorithm design: the art of computer programming

V. Vazirani said:

*Our philosophy on the design and exposition of algorithms is nicely illustrated by the following analogy with an aspect of Michelangelos's art: A major part of his effort involved looking for interesting pieces of stone in the quarry and staring at them for long hours **to determine the form they naturally wanted to take**. The chisel work exposed, in a minimal manner, this form.*

*By analogy, we would like to start with a clean, simply stated problem. Most of the algorithm design effort actually goes into **understanding the algorithmically relevant combinatorial structure of the problem**. The algorithm exploits this structure in a minimal manner..... with emphasis on stating the structure offered by the problems, and keeping the algorithms minimal.*

(See extra slides.)

- **DIVIDE-AND-CONQUER**: Let's start from the “smallest” problem first, and investigate whether a large problem can **reduce to smaller subproblems**.
- **“INTELLIGENT” ENUMERATION**: Consider an optimization problem. If the solution can be constructed step by step, we might enumerate **all possible complete solutions** by constructing a **partial solution tree**. Due to the huge size of the search tree, some techniques should be employed to prune it.
- **IMPROVEMENT**: Let's start from **an initial complete solution**, and try to improve it step by step.

The first example: calculating the greatest common divisor (gcd)

The first problem: calculating gcd

Definition (gcd)

The greatest common divisor of two integers a and b , when at least one of them is not zero, is the largest positive integer that divides the numbers without a remainder.

- Example:
 - The divisors of 54 are: 1, 2, 3, 6, 9, 18, 27, 54
 - The divisors of 24 are: 1, 2, 3, 4, 6, 8, 12, 24
 - Thus, $\gcd(54, 24) = 6$.

The first problem: calculating gcd

INPUT: two n -bits numbers a , and b ($a \geq b$)

OUTPUT: $\text{gcd}(a, b)$

- Observation: the problem size can be measured by using n ;
- Let's start from the “smallest” instance: $\text{gcd}(1, 0) = 1$;
- But how to efficiently solve a “larger” instance, say $\text{gcd}(1949, 101)$?

Problem instances

- Observation: a large problem can reduce to a smaller subproblem:
- $\text{gcd}(1949, 101) = \text{gcd}(101, 1949 \bmod 101) = \text{gcd}(101, 30)$

Strategy: reduce to “smaller” problems

Problem instances

- $\text{gcd}(101, 30) = \text{gcd}(30, 101 \bmod 30) = \text{gcd}(30, 11)$

Strategy: reduce to "smaller" problems

Problem instances

- $\gcd(30, 11) = \gcd(11, 30 \bmod 11) = \gcd(11, 8)$

Strategy: reduce to "smaller" problems

Problem instances

- $\gcd(30, 11) = \gcd(11, 8) = \gcd(8, 3) = \gcd(3, 2) = \gcd(2, 1) = \gcd(1, 0) = 1$

Sub-instance relationship graph

Problem instances

- Node: subproblems
- Edge: reduction relationship

```
1: function Euclid( $a, b$ )  
2: if  $b = 0$  then  
3:   return  $a$ ;  
4: end if  
5: return Euclid( $b, a \bmod b$ ) ;
```

Theorem

Suppose a is a n -bit integer. $\text{Euclid}(a, b)$ ends in $O(n^3)$ time.

Proof.

- There are at most $2n$ recursive calling.
 - Note that $a \bmod b < \frac{a}{2}$.
 - After two rounds of recursive calling, both a and b shrink at least a half size.
- At each recursive calling, the \bmod operation costs $O(n^2)$ time.

The second example: traveling salesman problem (TSP)

TSP: a concrete example

- In 1925, H. M. Cleveland, a salesman of the Page seed company, traveled 350 cities to gather order form.
- Of course, the shorter the total distance, the better.

How did they do? Pin and wire!

SECRETARIAL STUDIES

MAP SHOWING ROUTING OF SALESMEN BY PINS AND CORDS
Courtesy of Rand-McNally

- Two pictures excerpted from *Secretarial Studies*, 1922.

TRAVELLING SALESMAN PROBLEM

INPUT: n cities $V = \{1, 2, \dots, n\}$, and a distance matrix D , where d_{ij} ($1 \leq i, j \leq n$) denotes the distance between city i and j ;
OUTPUT: the shortest tour that visits each city exactly once and returns to the origin city.

- Tour 1: $1 \rightarrow 2 \rightarrow 3 \rightarrow 4 \rightarrow 1$ (distance: 12)
- Tour 2: $1 \rightarrow 2 \rightarrow 4 \rightarrow 3 \rightarrow 1$ (distance: 21)
- Tour 3: $1 \rightarrow 3 \rightarrow 2 \rightarrow 4 \rightarrow 1$ (distance: 23)
- Tour 4: $1 \rightarrow 3 \rightarrow 4 \rightarrow 2 \rightarrow 1$ (distance: 19)
- Tour 5: $1 \rightarrow 4 \rightarrow 2 \rightarrow 3 \rightarrow 1$ (distance: 23)
- Tour 6: $1 \rightarrow 4 \rightarrow 3 \rightarrow 2 \rightarrow 1$ (distance: 12)

Trial 1: divide and conquer

Consider a tightly related problem

Definition

$M(S, e)$ = the minimum distance, starting from city 1, visiting each city in S once and exactly once, and finishing at city e .

- There are 3 cases of the city from which we return to 1.
- Thus, the shortest tour can be calculated as:

$$\min \left\{ \begin{array}{l} d_{2,1} + M(\{3, 4\}, 2), \\ d_{3,1} + M(\{2, 4\}, 3), \\ d_{4,1} + M(\{2, 3\}, 4) \end{array} \right\}$$

Consider the smallest problem

- It is trivial to calculate $M(S, e)$ when S consists of only 1 city.

$$M(\{2\}, 3) = d_{12} + d_{23}$$

$$M(\{3\}, 2) = d_{13} + d_{32}$$

- But how to solve a larger problem, say $M(\{2, 3\}, 4)$?

Divide a large problem into smaller problems

- $M(\{2, 3\}, 4) = \min\{d_{34} + M(\{2\}, 3), d_{24} + M(\{3\}, 2)\}$

Problem instances

- A large problem can be reduced into smaller subproblems.

```
1: function  $TSP(V, D)$   
2: return  $\min_{e \in V, e \neq 1} M(V - \{e\}, e) + d_{e1};$ 
```

```
1: function  $M(S, e)$   
2: if  $S = \{v\}$  then  
3:    $M(S, e) = d_{1v} + d_{ve};$   
4:   return  $M(S, e);$   
5: end if  
6: return  $\min_{i \in S, i \neq e} M(S - \{i\}, i) + d_{ei};$ 
```

- Time complexity: $O(2^n n^2)$.

Trial 2: Improvement strategy

- Landscape of solution space:
 - Node: a complete solution. Each node is associated with an objective function value.
 - Edge: if two nodes are neighbors, an edge is added to connect them. Here "neighbours" refers to two nodes with small difference.
- Improvement strategy: start from a rough complete solution, and try to improve it step by step.

- Note that a **complete solution** can be expressed as a permutations of the n cities, e.g., 1, 2, 3, 4.
- Let's start from **an initial complete solution**, and try to improve it;

```
1: Let  $s$  be an initial tour;  
2: while TRUE do  
3:   select a new tour  $s'$  from the neighbourhood of  $s$ ;  
4:   if  $s'$  is shorter than  $s$  then  
5:      $s = s'$ ;  
6:   end if  
7:   if stopping( $s$ ) then  
8:     return  $s$ ;  
9:   end if  
10: end while
```

Here, **neighbourhood** is introduced to describe how to change an existing tour into a new one;

But how to define neighbourhood of a tour?

- 2-opt strategy: if s' and s differ at only two edges (Note: 1-opt is impossible)

An example

Step 1

- Initial complete solution $s: a \rightarrow b \rightarrow c \rightarrow d \rightarrow e \rightarrow a$
(distance: 25)

Step 2: a 2-opt operation improves $s \Rightarrow s'$

- Initial solution $s: a \rightarrow b \rightarrow c \rightarrow d \rightarrow e \rightarrow a$ (distance: 25)
- Improve from s to s' : $a \rightarrow b \rightarrow c \rightarrow e \rightarrow d \rightarrow a$ (distance: 23)

Step 3: One more 2-opt operation improves $s' \Rightarrow s''$

- A complete solution s' : $a \rightarrow b \rightarrow c \rightarrow e \rightarrow d \rightarrow a$ (distance: 23)
- Improve s' to s'' : $a \rightarrow c \rightarrow b \rightarrow e \rightarrow d \rightarrow a$ (distance: 19)
- Done! No 2-OPT can be found to improve further.

Trial 3: “Intelligent” enumeration strategy

Solution form

- Note that a complete solution can be expressed as a sequence of n edges. Given a certain order of the m edges, a complete solution can be represented as $X = [x_1, x_2, \dots, x_m]$, where $x_i = 1$ if the edge i was used in the tour, and $x_i = 0$ otherwise.
- For example, the tour $a \rightarrow b \rightarrow c \rightarrow d \rightarrow e \rightarrow a$ can be represented as $X = [1, 0, 0, 1, 1, 0, 0, 1, 0, 1]$.
- If the solution has this form, we can enumerate all possible complete solutions.

Organizing solutions into a partial solution tree

- Partial solution tree:

- Leaf node: representing **a complete solution** associated with an objective function value, e.g., $X = 1011000011$ has an objective function value of 23.
- Internal node: representing **a partial solution**, where only a subset of items (in the path from root to the node) are known, e.g., $X = 10????????$ refers to tours including $e_1 : (a, b)$ but excluding $e_2 : (a, c)$.

Two alternative views of a partial solution

- A subproblem: to determine the **unknown items**, e.g., $X = 10?????????$ means to find the shortest tour including $e_1 : (a, b)$ but excluding $e_2 : (a, c)$.
- A collection of complete solutions: the leaf nodes of the subtree rooted at this partial solution, e.g., $X = 101?0?????$ represents two nodes in red 1011000011 and 1010001110 .

Deduction rules for simplification

- Note that the following deduction rules were applied for simplification.
 - An edge (i, j) should be included in the tour if the removal of this edge leads to less than two edges incident to i or j , e.g., $x_8 = 1$ in $X = 1010001110$.
 - An edge (i, j) should be excluded from the tour if the addition of this edge leads to more than two edges incident to i or j , or leads to a small circuit, e.g., $x_5 = 0$ in $X = 101?0?????$.

Enumerate all complete solutions: Backtrack algorithm

```
1: Let  $A = \{P_0\}$ . //Start with the original problem  $P_0$ . Here,  $A$ 
   denotes the active subproblems that are unexplored.
2:  $best\_so\_far = \infty$ ;
3: while  $A \neq NULL$  do
4:   choose and remove a subproblem  $P$  from  $A$ ;
5:   expand  $P$  into smaller subproblems  $P_1, P_2, \dots, P_k$ ;
6:   for  $i = 1$  to  $k$  do
7:     if  $P_i$  corresponds to a complete solution then
8:       update  $best\_so\_far$  if the corresponding objective function
       value is better;
9:     else
10:      insert  $P_i$  into  $A$ ;
11:    end if
12:  end for
13: end while
14: return  $best\_so\_far$ ;
```

An example: Step 1

Partial Solution Tree

○ $X = ??????????$
 P_0

- Initially, the partial solution tree has only one root node, i.e., the original problem P_0 . The value $best_so_far$ is set as $+\infty$.

Partial Solution Tree

- P_0 is decomposed into two subproblems P_1 and P_2 . We then expand P_1 at the next step.

Step 3

Partial Solution Tree

- At this stage P_3 was selected for expansion.

Step 4

- In this way all possible complete solutions can be enumerated step by step, and it is unnecessary to store the whole tree in memory, thus reducing space requirement.
- Note that some internal nodes, say P_5 , can be removed as the corresponding edges cannot form a valid tour.
- Theoretically speaking it will take exponential time to enumerate all possible complete solutions.
- Question: can we make the enumeration efficient?

Speeding up enumeration process by pruning branches

- Basic idea: to speed-up enumerating process, a feasible way is to prune branches at some internal nodes with “low quality”. That is, **partial solutions can be exploited to exclude some complete solutions**. The representatives of this strategy include greedy method and branch-and-bound.
- Note that only complete solutions are associated with objective function value. Thus, how to estimate quality of a partial solution?
 - In greedy approaches, **heuristic functions** are used to estimate objective function value for a partial solution.
 - In branch-and-bound approaches, **lower bound functions** are used to calculate the lower bound of objective function value of a partial solution, i.e., the objective function value of all complete solutions represented by this partial solution.

Calculate lower bound for partial solution: an example

- For the partial solution $X = \text{????????}$, we estimate the shortest tour as below:
 - for each city, we select the shortest two adjacent edges;
 - the sum of these $2n$ edges is less than 2 times the optimal tour;
 - thus, we can give a lower bound as $\frac{1}{2}(5 + 6 + 8 + 7 + 9) = 17.5$.
- Similarly, the lower bound for the partial solution $X = 10\text{????????}$ was estimated as $\frac{1}{2}(5 + 6 + 9 + 7 + 9) = 18$.

“Intelligent” enumeration

```
1: Let  $A = \{P_0\}$ . // Start with the original problem  $P_0$ . Here  $A$ 
   denotes the active subproblems that are unexplored.
2:  $best\_so\_far = \infty$ ;
3: while  $A \neq NULL$  do
4:   choose a subproblem  $P \in A$  with lower bound less than
      $best\_so\_far$ ;
5:   Remove  $P$  from  $A$ ;
6:   expand  $P$  into smaller subproblems  $P_1, P_2, \dots, P_k$ ;
7:   for  $i = 1$  to  $k$  do
8:     if  $P_i$  corresponds to a complete solution then
9:       update  $best\_so\_far$ ;
10:    else
11:      if  $lowerbound(P_i) \leq best\_so\_far$  then
12:        insert  $P_i$  into  $A$ ;
13:      end if
14:    end if
15:  end for
16: end while
17: return  $best\_so\_far$ ;
```

An example: Step 1

Partial Solution Tree

○ $X = ??????????$
 $P_0(17.5)$

- Initially, the partial solution tree has only one root node, i.e., the original problem P_0 (lower bound: 17.5). The value $best_so_far$ is set as $+\infty$.

Partial Solution Tree

- P_0 is decomposed into two subproblems P_1 and P_2 , and lower bounds of these two subproblems are estimated accordingly.
- As P_1 has a smaller lower bound than P_2 , P_1 will be chosen to expand at the next step.
- Here, we adopt a rule to choose the subproblem with the smallest lower bound with the hope to find the optimal solution as soon as possible.

Step 3

Partial Solution Tree

- P_4 has the smallest lower bound; thus, it will be chosen for expansion.

Step 4

$A = \{P_2, P_3, P_5, P_6\}$
 $best_so_far = +\infty$

Partial Solution Tree

- P_5 has the smallest lower bound; thus, it will be chosen for expansion.

Step 5

$A = \{P_2, P_3, P_6\}$
 $best_so_far = 21$

Partial Solution Tree

Two complete solutions, P_7 and P_8 , are obtained, and $best_so_far$ is updated as 21. P_3 and P_6 should be removed, and P_2 will be chosen for expansion.

Step 6

$A = \{P_9\}$
best_so_far = 21

Partial Solution Tree

P_{10} should not be added into A , and P_9 is chosen for expansion.

$A = \{P_{11}\}$
best_so_far = 21

Partial Solution Tree

P_{12} should not be added into A , and P_{11} will be expanded.

Final step

$A = \{\}$
best_so_far = 19

Partial Solution Tree

Note: the tree was pruned to contain only 14 nodes, making the algorithm efficient

BACKTRACKING strategy: another trial

- Another solution form: Note that a tour can also be expressed as a sequence of n nodes, i.e., $X = [x_1, x_2, \dots, x_{n-2}]$, where $x_i \in V$. Without loss of generality, we assume $x_1 = a$, and b should appear before c in the tour. For example, the tour in blue can be represented as $X = abcd$.
- As solutions have this form, we can enumerate them through building a partial solution tree together with pruning technique.

An example: Step 1

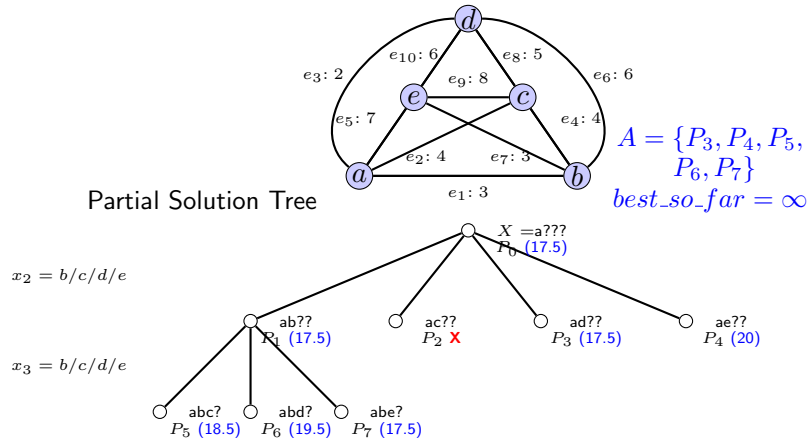

Initially, we have only one active sub-problem P_0 with lower bound of tour distance 17.5. P_0 will be expanded at the next step.

Step 2

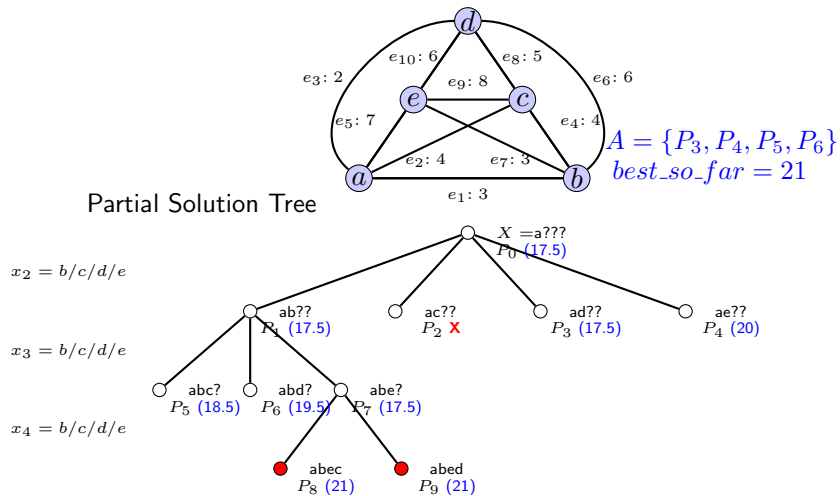

Note that the partial solution $X = ac??$ was abandoned as we assume b appears before c in the tour. P_1 will be expanded at the next step.

Step 3

P_7 will be expanded at the next step.

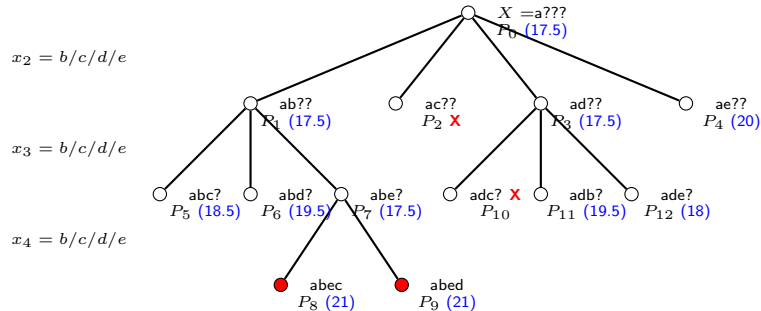

We obtained two complete solutions, and updated *best_so_far* accordingly. P_3 will be expanded.

Step 5

Partial Solution Tree

P_{12} will be expanded at the next step.

Final step

Note: the tree was pruned to contain only 15 nodes, making the algorithm efficient.

Time complexity and space complexity

- Time (space) complexity of an algorithm quantifies the time (space) taken by the algorithm.
- Since the time costed by an algorithm grows with the size of the input, it is traditional to describe running time as a function of the input size.
 - **Input size:** The best notation of input size depends on the problem being studied.
 - For the TSP problem, the **number of cities in the input**.
 - For the MULTIPLICATION problem, the **total number of bits** needed to represent the input number is the best measure.

Running time: we are interested in its growth rate

- A straightforward way is to use the exact seconds that a program used. However, this measure highly depends on CPU, OS, compiler, etc.
- Several simplifications to ease analysis of algorithm:
 - ① We simply use the number of primitive operations (rather than the exact seconds used) under the assumption that a primitive operation costs constant time. Thus the running time is $T(n) = an^2 + bn + c$ for some constants a, b, c .
 - ② We consider only the leading term, i.e. an^2 , since the lower order terms are relatively insignificant for large n .
 - ③ We also ignore the leading term's coefficient a since it is less significant than the growth rate.
- Thus, we have $T(n) = an^2 + bn + c = O(n^2)$. Here, the letter O denotes **order**.

- Recall that big O notation is used to describe the **error term** in Taylor series, say:

$$e^x = 1 + x + \frac{x^2}{2} + O(x^3) \text{ as } x \rightarrow 0$$

Figure 2: Example: $f(x) = O(g(x))$ as there exists $c > 0$ (e.g. $c = 1$) and $x_0 = 5$ such that $f(x) < cg(x)$ whenever $x > x_0$

- In 1976 D.E. Knuth published a paper to justify his use of the Ω -symbol to describe a stronger property. Knuth wrote: "For all the applications I have seen so far in computer science, a stronger requirement [...] is much more appropriate".
- He defined

$$f(x) = \Omega(g(x)) \Leftrightarrow g(x) = O(f(x))$$

with the comment: "Although I have changed Hardy and Littlewood's definition of Ω , I feel justified in doing so because their definition is by no means in wide use, and because there are other ways to say what they want to say in the comparatively rare cases when their definition applies".

- Big Θ notation is used to describe " $f(n)$ grows asymptotically as fast as $g(n)$ ".

$$f(x) = \Theta(g(x)) \Leftrightarrow g(x) = O(f(x)) \text{ and } f(x) = O(g(x)).$$

Worst case and average case

- Worst-case: the case that takes the longest time;
- Average-case: we need know the distribution of the instances;
